Print() displays output on the screen. print("Python is cool"). Commas put a space between values. They are used to put a space between values when outputting print("choice", "Angel"). print() gives a blank line. Print("="*25) gives us a multiplied string so the line of code will have 25 =. A variable is used to store data. We read = as gets. subject = "computer". When naming variables we can use underscores but there should be no spaces. Variables are also case sensitive. We cannot use names related to Python as well like print. Every value has a type. each text is put in quotation marks and the type is string. Whole numbers are int and decimals are float. value = "Python" → str ; number = 100 → int ; order = 10.1 → float We can convert between types because when a user inputs Python always enters text/string so we can convert to float or int. number = float(input("Please enter number")). We can also use + to concatenate string in Python. print("20" + "20" + "20") → 202020 We can use f-strings to format our print. print(f"The number is: {number:>10.2f}") → The number is +20.00. This means the number 20 will be right aligned in 10 spaces, have a sign and 2 decimal places.
